DEDICATION

Just hoping this is useful!

Chapter 1

Introduction

The vulnerability of the software enable the exploitation of the computer or system it is running on. Wherefore, the emphasize placed on computer security particularly in the field of software vulnerabilities increase dramatically along with the grow of the internet. It's important for software developers to build secure applications. Assurance about the integrity and security of the software are expected from the vendors of the software. Unfortunately, building secure software is expensive. The vendors usually comply with their own quality assurance measures which focus on marketable concerns while left security in lower priority or even worse, totally ignore it. Therefore, fully relying on the vendor of the software to secure your system and data is unpractical and risky.

Software security review conducted by a third party is usually more convincing and reliable. One approach of software security review is software auditing. It is a process of analyzing the software in forms of source code or binary. This auditing can uncover some hard to reveal vulnerabilities which might be exploited by the hackers. Identification of these security holes can save the users of the software from putting their sensitive data and business resources at risk.

Most of the software vulnerabilities are caused by malicious data intrusion. So it is valuable to understand how this malicious data trigger the unexpected behaviors of the system. In most of the cases, this malicious data is injected by attackers into the system to trigger the exploitation. Nonetheless, this malicious data might go through devious path to ultimately trigger an exploitable condition of the system. In some complicated system, several components which are collaborated programs work together to provide service or functionality. In these situation, the malicious data might have passed through multiple components of the system and be modified before it reach the vulnerable point of the system. As a consequence, the flow of data throughout the system's different programs is considered to be one of the most important attribute to analysis during the security review.[6]

The data flow among various programs with in the system or across different systems helps to understand how the system work as well as disclose the vulnerabilities of the system as stated before. There are multiple mechanism to grab the data across programs. And the methods for obtaining this data flow is essential and can affect the analysis result greatly.

In this research, I developed a method to analysis communications between the programs by the analysis of the execution traces of them. I didn't aim at covering all the communication types but only focus on the data exchanging ones. This method can guide the security engineers to investigate the communications of the programs in the circumstance that they have the captured execution traces and want to understand the interaction behavior of the programs. The research is not specified for vulnerabilities detection but generalized for the comprehension of the behavior of the programs.

1.1 Motivation

This project started with an informal requirement from DRDC for visualizing multiple assembly traces to assist their software and security analysis. The literature review and the conversation with DRDC help to clarify the goal and target of this research. In this section, I discuss the need of performing assembly trace investigation for communication analysis. First I explain why the security engineers perform assembly trace analysis. Then I elaborate why they need to perform communication analysis at assembly trace level.

1.1.1 Why Assembly Trace Analysis

Dynamic analysis of program is adopted mainly in software maintenance and security auditing[24], [4], [19]. Sanjay Bhansali et al. claimed that program execution traces with the most intimate detail of a program's dynamic behavior can facilitate the program optimization and failure diagnosis. Jonas Trümper et al. give a example of how tracing can facilitate software-maintenance tasks [21].

The dynamic analysis can be done by using debuggers, however, debuggers would halt the execution of the system and result in a distortion of the timing behavior of the running system [21]. Instead, tracing a running program with instrumentation would provide more accurate run time behavior information about the system.

The instrumentation of the tracing can be in various levels, such as programming language or machine language levels. The choice in some how depends on the accessibility to the application. The application access is divided into five categories with variations: source only, binary only, both

source and binary access, checked build, strict black box. Binary only category is common when performing vulnerability research on closed-source commercial software.[6] In this case, assembly level tracing provides the possibility of the security review of the software.

On the other hand, since the binary code is what is running on the system, it is more representative of actual situation than the source code. Some bugs might appear because of a compilation problem or because the compiler optimized away some code that was necessary to make the system secure. A piece of code listed below is an example in which the line of code resetting the password before the program end would be optimized away by GNU Compiler Collection(GCC) due to it is not used later. This made the user's password stayed in memory, which is considered as a security flaw. However, by looking at the source code didn't reveal that problem.

Listing 1.1: Password Fetching Example

```
#include <iostream>
#include <string>
#include <conio.h>
using namespace std;
int main(){
  string password ="";
  char ch;
  cout << "Enter password";
  ch = \_getch();
  while(ch != 13){//character 13 is enter
    password.push_back(ch);
    cout << ' *';
    ch = _getch();
  if (checkPass(password)) {
   allowLogin();
  password ="";
```

1.1.2 Why Communication Analysis with Assembly Traces

Programs nowadays do not alway work isolated, many software appear as reticula collaborating systems connecting different modules in the network[16] which make the discovery of vulnerabilities even harder. The communication and interaction between modules affect the behavior of the software. Without regarding to the synergy information, analysis of the isolated execution trace on a single computer is usually futile. The tracing data flow process is essential to reviews of both the design and implementation of software.

Many network sniffer such as Wireshark[5] and Tcpdump[20] can help to capture the data flow

across the network which make the systematic analysis possible. However, it is claimed as the insufficient method due to the fact that security problems can occur even if the information sent is correct. Therefore, analyzing the communications with transmitted data in instruction and memory access level is a solid way to evaluation the system.

Shameng Wen et al. argued that fuzz testing and symbolic execution are widely applied to detect vulnerabilities in network protocol implementations. They present their model-guided approach to detect vulnerabilities in the network protocol implementation. Their work focus on designing the model which guide the symbolic execution for the fuzz testing but ignoring the analysis of the output, which is the execution traces. [22] Further more, their work focus only on the network protocol implementation but not generalized to all communications, including network protocol and inter process communications.

Besides vulnerabilities detection and security reason, communication analysis with assembly traces can also be a way to learn how the work is performed by the system or sometime validate a specification of it. Our research partner DRDC provided some use cases in which they require the assistance of communication analysis to understand their systems. The first one is related to their work with the embedded systems. These systems often have more than one processor, each specialized for a specific task, that coordinate to complete the overall job of that device. In the other case, the embedded device will work with a normal computer and exchange information with it through some means (USB, wireless, etc.). For instance, the data might be coming in from an external sensor in an analog form, transformed by a Digital Signal Processor (DSP) in a device, sent to a more generic processor inside that device to integrate with other data then send wireless to an external computer. Being able to visualize more than one trace would help them follow the flow of data through the system.

1.2 Research Goal

The goal of this research is to design a method for communication analysis using the execution traces of the interacting programs. This method should be general enough for all message based communication analysis between programs regardless of their programming language, host operating system or selected execution tracer.

1.3 Research Process

Figure 1.1 shows the overview of my research process with three abstracted stages. However, The approach of this research is not a forthright process. Instead, it is a back and forth one, for example the implementation changed several times with the changes of the model, and the models was modified based on the understanding throughout the implementation.

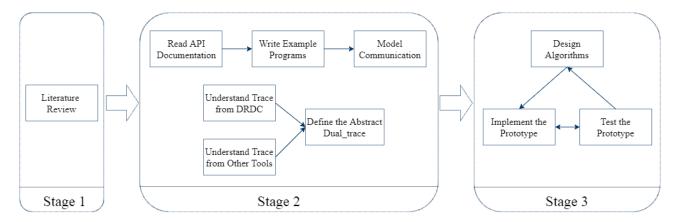

Figure 1.1: Research Approach overview

This research requires background knowledge in three major fields: 1)software security, 2)program communication mechanisms and implementations, 3)program trace in assembly level. I acquired the background knowledge basically from literature review. It helps me to grab the essential concept of software vulnerabilities and their categories, understand some facilities for vulnerabilities detection and software maintenance in the perspective of security. After that, I was convinced that communication analysis in assembly trace level would benefit software security engineers to understand to behavior of the software and detect software vulnerabilities.

In order to analysis the communication of programs, I had to know how the communication works. For this purpose, I started the investigation from a piratical experiment by writing example simple programs with the Windows API and run them locally in my desktop. By understanding their behavior and the reading of the Windows API documentation, I abstracted the communication model which is not operating system specified.

The abstract assembly trace definition was build on the generalization of the trace format provided by our research partner, DRDC. I don't have the access to their home-made assembly tracer which is based on PIN[11]. Fortunately, they provides a comprehensive document about the format of the captured trace and example traces to me. With these, I grasped the constructive view of the assembly execution trace. Further more, in the present of some dynamic software analysis works

[9], [14], [18], [1], [2] and [21], it is certain that, some other tools can also capture the required information in assembly level for communication analysis. This supports the generalization of the trace definition and the abstraction of the dual_trace.

The implementation of the prototype and the communication identification algorithms are develop in parallel. The high level identification algorithm and the specific algorithms for named pipe communication methods were abstracted based on the implementation, while the others are developed theoretically. Two experiments are designed to test the prototype and some algorithms.

1.4 Contribution

The main contributions of these work can be summarized as:

- Communication Model: The communication model in this thesis is an abstract model of
 the communications between two programs. It was abstracted from the understanding of
 several communication methods and is general for other communication methods that are
 not mention in this thesis.
- **Dual_trace Formalization:** By understanding the assembly level execution traces, a dual_trace was formalized to describe the information that needed for communication analysis. This model doesn't specify the format of the execution traces but defines what information is necessary to be contained to fulfil the analysis requirement. All execution traces comply with this definition can be used for the analysis.
- Communication Identification Approach: The overall approach to identify the communication of a communication method is designed. Some algorithms are developed for the steps in this approach regarding to some communication methods or communication categories.
- **Feature Prototype:** A feature prototype is designed and implemented on Atlantis to test and prove the communication identification approach.

1.5 Thesis Organization

In Chapter 2, I summarize the related background information and knowledge needed to understand or related to this work including security and vulnerability, program communication mechanisms, program execution trace tools, and Atlantis.

Chapter 3 depicts the model of the communication between two programs. The communication model defines the communication in the context of trace analysis as well as discusses the properties of the communications.

Chapter 4 presents the abstract dual_trace definition. Based on this definition, I developed the communication identification process and the essential algorithms.

To provide more concrete idea, I present, in chapter 5, the implemented communication identification feature prototype. This prototype was built on top of Atlantis[10], an assembly execution trace analysis environment.

In chapter 6, I present two experiments of communication analysis with dual_traces of programs using the implemented prototype. Notably, the result shows the communications are correctly identified.

Finally, In chapter 7, I conclude the result of this research and outline the possible future work.

Chapter 2

Background

In this section, I summarize the background knowledge or information that related to this work. First I generally describe software vulnerability. Second, I discuss the general definition of communication among programs and their categorization. Third, I introduce some tools for assembly level program debugging and analysis. Finally I introduce Atlantis, the existing assembly level execution trace analysis environment, on which the implementation of this work based.

2.1 Software Vulnerability

Software vulnerability detection is one of the use cases of the communication analysis with assembly level execution traces. The understanding of fundamentals of software vulnerability is necessary to comprehend some implicit concepts or design intention through out this thesis.

Vulnerabilities, from the point of view of software security, are specific flaws or oversights in a program that can be exploited by attackers to do something malicious expose such as modify sensitive information, disrupt or destroy a system, or take control of a computer system or program. They are considered to be a subset of bugs. Input and Data Flow, interface and exceptional condition handling where vulnerabilities are most likely to surface in software and memory corruption is one of the most common vulnerabilities. The awareness of these two facts would make the security auditing and vulnerabilities detection have more clear focus. [6]

2.2 Program Communications

Programs can communicate with each other via diverse mechanisms. The communication happens among processes is known as inter-process communication. This refers to the mechanisms an

operating system provides the process to share data with each other. It includes methods such as signal, socket, message queue, shared memory and so on.[8] This communications can happen over network or inside a device. Based on their reliability, the communication methods can be simply divided into two categories: reliable communication and unreliable communication. In this work, communication methods belong to all both categories has been covered. However, I only discuss the message based communication methods while leave the control based communication, like remote function call for the future.

2.3 Program Execution Tracing in Assembly Level

The communication analysis discuss throughout this thesis is based on the assembly traces. Thurs capturing of the execution traces became a prerequisite of this work. DRDC has its own homemade tracer, the traces from which are used in the experiments of this research. However, the model and algorithms developed in this research is not limited with this specific home-made tracer. Any tracer that can capture sufficient information according to the model can serve this purpose.

There are many tools that can trace a running program in assembly instruction level. IDA pro [7] is a widely used tool in reverse engineering which can capture and analysis system level execution trace. Giving open plugin APIs, IDA pro allows plugin such as Codemap [12] to provide more sufficient features for "run-trace" visualization. PIN[11] as a tool for instrumentation of programs, provides a rich API which allows users to implement their own tool for instruction trace and memory reference trace. Other tools like Dynamic [3] and OllyDbg[23] also provide the debugging and tracing functionality in assembly level.

2.4 Atlantis

Atlantis is a trace analysis environment developed in Chisel. It can support analysis for multigigabyte assembly traces. There are several features distinct it from all other existing tools and make it particularly successful in large scale trace analysis. These features are 1) reconstruction and navigation the memory state of a program at any point in a trace; b) reconstruction and navigation of system functions and processes; and c) a powerful search facility to query and navigate traces. The work of this thesis is not a extension of Atlantis. But it take advantages of Atlantis by reusing it existing functionality to assist the dual_trace analysis.

Chapter 3

Communication Modeling

In this chapter, I depict the model of the communication of two running programs from the trace analysis point of view. The modeling is based on the investigation of some common used communication methods. But the detail of the communication methods will be discussed later in the algorithm and implementation chapters. This chapter only present the abstract communication model regarding to the two communication categories: reliable and unreliable communications.

3.1 Communication Methods Categorization

In general, in the terms of their reliability of data transmission, there are two types of communication: reliable and unreliable. A reliable communication guarantees the data being sent by one endpoint through the channel is always received losslessly and in the same order in the other endpoint. On contrast, an unreliable communication does not guarantee the data being sent always arrive the receiver. Moreover, the data packets can arrive to the receiver in any order. However, the bright side of unreliable communication is that the packets being sent are always arrived as the origin packet, no data re-segmentation would happen. An endpoint is an instance in a program at which a stream of data is sent or a stream of data is received or both (e.g. socket handle of TCP or a file handle of the named pipe). A channel is a conduit connected two endpoints through which data can be sent and received. Table3.1 gives examples of communication methods fall in these two categories.

Table 3.1: Communication Method Examples in Two Categories

Reliable Communication	Unreliable Communication
Named Pipes	Message Queue
TCP	UDP

3.2 Communication Model

The communication of two programs is defined in this section. The communication in this work is data transfer activities between two running programs through a specific channel. Some collaborative activities between the programs such as remote procedure call is out of the scope of this research. Communication among multiple programs (more than two) is not discussed in this work. The channel can be reopened again to start new communications after being closed. However, the reopened channel is considered as a new communication. The way that I define the communication is leading to the communication identification in the dual-trace. So the definition is not about how the communication works but what it looks like. There are many communication methods in the real world and they are compatible to this communication definition.

3.2.1 Communication Definition

In the context of a dual_trace, a communication is a sequence of data transmitted of two endpoints through a communication channel. The endpoints connect to each other using the identifier of this channel. We therefore defined a communication c as a triplet:

$$c = \langle ch, e_0, e_1 \rangle$$

where e_0 and e_1 are endpoints while ch is the communication channel (e.g. a named piped located at /tmp/pipe).

From the point of view of traces, the endpoints e_0 and e_1 are defined in terms of three properties: the handle created within a process for the endpoint for subsequent operations(e.g. data send and receive), the data stream received and the data stream sent. Therefore, I define an endpoint e as a triplet:

$$e = \langle handle, d_r, d_s \rangle$$

where handle is the handle identifier of the endpoint, d_r and d_s are data streams. A data stream is a sequence of sent packages or a sequence of received packages. Each package pk contains data that is being sent or received (its payload). Hence, we can define a data stream d as a sequence of n packages:

$$d = (pk_1, pk_2, ..., pk_n)$$

Note: This is the sequence of packages as seen from the endpoint and might be different than the sequence of packages seen in the other endpoint, specially where there is package reordering, loss or duplication.

Each package pk has two attributes:

• *Relative time(it was sent or received):* In a trace, we do not have absolute time for an event. However, we know when an event (i.e. open, close, sending or receiving a package) has happened with respect to another event. I will use the notation

```
time(pk)
```

to denote this relative time. Hence,

if
$$i < j$$
, then $time(pk_i) < time(pk_j)$

• Payload: Each package has a payload (the data being sent or received). I use the notation pl(pk)

to denote this payload.

3.2.2 Communication Properties

The properties of the communications can be described based on the definition of the communication.

Properties of reliable communication:

A reliable communication guarantees that the data sent and received between a package happens without loss and in the same order.

For a given data stream, I define the data in this stream as the concatenation of all the payloads of all the packages in this stream, in the same order, and denote it as data(d).

Given
$$d = \langle pk_1, pk_2, ..., pk_n \rangle$$
, $data(d) = pl(pk_1) \cdot pl(pk_2) \cdot ... \cdot pl(pk_n)$

• Content Preservation: for a communication:

$$c = \langle ch, \langle h_0, dr_0, ds_0 \rangle, \langle h_1, dr_1, ds_1 \rangle \rangle$$

the received data of an endpoint should always be a prefix of (potentially equal to) the sent data of the other:

$$data(dr_0)$$
 is a prefix of $data(ds_1)$ and

 $data(dr_1)$ is a prefix of $data(ds_0)$

• *Timing Preservation:* at any given point in time, the data received by an endpoint should be a prefix of the data that has been sent from the other:

```
for a sent data stream of size m, ds = \langle pks_1, pks_2, ...pks_m \rangle that is received in data stream of size n, dr = \langle pkr_1, pkr_2, ...pkr_n \rangle for any k \in 1...n, there must exist j \in 1...m such that:

pks_j was sent before pkr_j was received: time(pks_j) < time(pkr_j)
```

 pks_j was sent before pkr_k was received: $time(pks_j) < time(pkr_k)$

and

$$data(\langle pkr_1, pkr_2, ..., pkr_k \rangle)$$
 is a prefix of $data(\langle pks_1, pks_2, ..., pks_i \rangle)$

In other words, at any given time, the recipient can only receive at most the data that has been sent.

Properties of unreliable communication:

In unreliable communication the properties are not concerned in the concatenation of packages. Instead, each package is treated as independent of each other.

• Content Preservation: a package that is received should have been sent:

for a sent data stream of size m, $ds = \langle pks_1, pks_2, ...pks_m \rangle$ that is received in data stream of size n, $dr = \langle pkr_1, pkr_2, ...pkr_n \rangle$

for any $pkr_i \in dr$ there must exist $pks_i \in ds$

We will say that the pkr_j is the matched package of pks_i , and vice-versa, pks_i is the matched package of pkr_j , hence

$$match(pkr_j) = pks_i$$
 and $match(pks_i) = pkr_i$

• *Timing Preservation:* at any given point in time, packages can only be received if they have been sent

for a sent data stream of size $m, ds = \langle pks_1, pks_2, ...pks_m \rangle$ that is received in data stream of size $n, dr = \langle pkr_1, pkr_2, ...pkr_n \rangle$

for any
$$k \in 1..n$$
, $time(match(pkr_i)) < time(pkr_i)$

In other words, the match of the received package must has been sent before it is received.

In the following two examples, h_0 and h_1 are the handles of the two endpoints e_0 and e_1 of the communications. ds_0 , dr_0 and ds_1 , dr_1 are the data streams of the endpoints e_0 and e_1 . The payloads are the strings represented in blue and red in the figures.

Figure 3.1 is an example of the reliable communication.

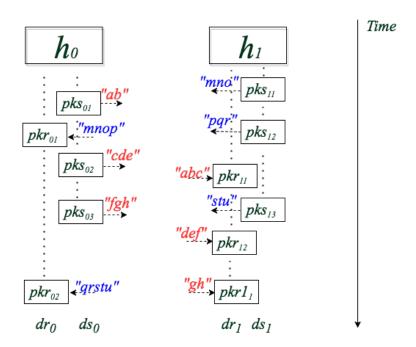

Figure 3.1: Example of Reliable Communication

In this example, the payloads of the packages are:

$$\begin{array}{l} pl(pks_{01})=\text{``ab''}, pl(pks_{02})=\text{``cde''}, pl(pks_{03})=\text{``fgh''};\\ pl(pkr_{11})=\text{``abc''}, pl(pkr_{12})=\text{``def''}, pl(pkr_{13})=\text{``gh''}.\\ \text{and}\\ pl(pks_{11})=\text{``mno''}, pl(pks_{12})=\text{``pqr''}, pl(pks_{13})=\text{``stu''};\\ pl(pkr_{01})=\text{``mnop''}, pl(pkr_{02})=\text{``qrstu''}.\\ \text{on the other direction}. \end{array}$$

Their properties:

$$\begin{split} pl(pks_{01}) \cdot pl(pks_{02}) \cdot pl(pks_{03}) &= pl(pkr_{11}) \cdot pl(pkr_{12}) \cdot pl(pkr_{13}) = \text{``abcdefgh''} \\ \text{and} \\ pl(pks_{11}) \cdot pl(pks_{12}) \cdot pl(pks_{13}) &= pl(pkr_{01}) \cdot pl(pkr_{02}) = \text{``mnopqrstu''}. \\ \text{satisfy the content preservation.} \end{split}$$

The relative time relationship of the packages are:

$$time(pks_{01}) < time(pks_{02}) < time(pkr_{11}) < time(pks_{03}) < time(pkr_{12}) < time(pkr_{13});$$

```
time(pks_{11}) < time(pks_{12}) < time(pkr_{01}) < time(pks_{13}) < time(pkr_{02}). The fact that pl(pkr_{01}) = \text{``mnop''} \text{ is the prefix of } pl(pks_{11}) \cdot pl(pks_{12}) = \text{``mnopqr''}, pl(pkr_{01}) \cdot pl(pkr_{02}) = \text{``mnopqrstu''} \text{ is the prefix of (in this case is identical to ) } pl(pks_{11}) \cdot pl(pks_{12}) \cdot pl(pks_{13}) = \text{``mnopqrstu''}, pl(pkr_{11}) = \text{``abc''} \text{ is the prefix of } pl(pks_{01} \cdot pl(pks_{02}) = \text{``abcde''}, pl(pkr_{11}) \cdot pl(pkr_{12}) = \text{``abcdef''} \text{ and } pl(pkr_{11}) \cdot pl(pkr_{12}) \cdot pl(pkr_{13}) = \text{``abcdefgh''} are the prefix of pl(pks_{01}) \cdot pl(pks_{02}) \cdot pl(pks_{03}) = \text{``abcdefgh''} satisfy the timing preservation.
```

Figure 3.2 is an example of the unreliable communication.

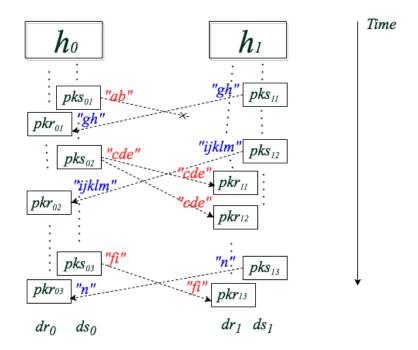

Figure 3.2: Example of Unreliable Communication

In this example, the content preservation of the unreliable communication are satisfied since:

```
pkr_{11} = pks_{02} = "cde";

pkr_{12} = pks_{02} = "cde";

pkr_{13} = pks_{03} = "fi";

pkr_{01} = pks_{11} = "gh";

pkr_{02} = pks_{12} = "ijklm";

pkr_{03} = pks_{13} = "n".
```

while the timing preservation of the unreliable communication are satisfied since:

```
time(pkr_{11}) > time(pks_{02});

time(pkr_{12}) > time(pks_{02});

time(pkr_{13}) > time(pks_{03});

time(pkr_{01}) > time(pks_{11});

time(pkr_{02}) > time(pks_{12});

time(pkr_{03}) > time(pks_{13});
```

Chapter 4

Communication Identification

The goal of this work is to identify the communications from the dual_trace. A dual_trace is a pair of assembly level execution traces of two interacting programs. In this chapter, I discuss the characteristics of the execution trace and give the abstract definition of the dual_trace and the execution trace. For all traces comply with this abstract trace definition, the analysis approach presented in this chapter can be applied for the communication identification.

The process of the communication identification is shown in Figure 4.1. It takes the two traces $trace_0$ and $trace_1$ in the dual_trace as input and output the identified communications. In this overview figure, there are four components. The function call event reconstruction component will take $trace_0$ and $trace_1$ as input and reconstruct the function call of interest from them respectively. The output sequences of events etr_0 and etr_1 will then flow into the stream extraction component separately. The stream extraction component will extract two sets of streams str_0 and str_1 . Each stream in these two set corresponding to an endpoint of a communication. After that, the stream matching component will take both of the stream sets as input and try to match them by their channel identifiers and output the potential identified communications cs. Finally, the data verification component will verify each communication c in this set and filter out those who doesn't satisfy the communication data preservation. The final output cs is the identified communications from the whole process. Algorithms are designed separately for each component.

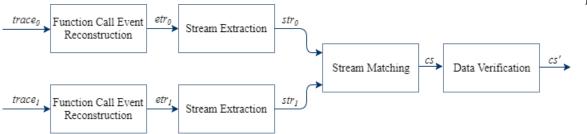

Figure 4.1: Process of the Communication Identification from a Dual_trace

4.1 Dual_Trace

A dual_trace consists of two assembly level execution traces of two interacting programs. There is no timing information of these two traces which means we don't know the timing relationship of the events of one trace with respect to the other. However the captured instructions in the trace are ordered in execution sequence. An execution trace consist of a sequence of instruction lines. Each instruction line contains the executed instruction, the changed memory, the changed registers, execution information. The execution information indicates the execution type which can be: Instruction, System call entry, System call exit, etc. For the execution type of system call entry and system call exit, system call Id is given in this information. With the system call id and the provided .dll files, a called system function name can be obtained.

A dual_trace is formalized as:

```
dual\_trace = \{trace_0, trace_1\}
```

where $trace_0$ and $trace_1$ are two assembly execution traces.

A trace is a sequence of executed instruction line. Hence, I define a trace as a sequence of n instruction lines:

```
trace = (l_1, l_2, ..., l_n)
```

Each instruction line, l is a tuple:

$$l = \langle ins, mch, rch, exetype, syscallInfo \rangle$$

where ins is the instruction, mch is the memory changes, rch is the register changes, exetype is the execution type which can be instruction, system call entry, system call exit, and other types which are not concerned in this work, $syscallInfo = \langle exeName, offset \rangle$ only appear when exetype is system call entry or system call exit. exeName is the executable file name(e.g. .dll and .exe), while offset is the offset of the system function in this executable file.

Figure 4.2 is an example of a piece of execution trace complying to this definition.

					19
Line	Instruction	Memory Changes	Regitster Changes	Execution Type	System Call Info
l_{1499} l_{1500}	<pre>lea rcx, ptr [rip+0x3cfe0] xor r9d, r9d</pre>		ECX F8A0AAA8	Instruction Instruction

Figure 4.3: Information of kernal32.dll

4.2 Function Descriptor

There would be lots of function calls in an execution trace. However, most of them are not of interest. We only concern the function call events of a specific communication method. To be able to identify and reconstruct the functions of interest, the function descriptions is required. Hence, I define the function descriptor as a set of function description:

```
cdesc = \{fdesc_1, fdesc_2, ..., fdesc_p\}
Each element fdesc can be defined as:
fdesc = \{name, type, inparamdesc, outparamdesc\}
```

where, *name* is the function name, *type* is the function type which can be one of the four types: *open*, *close*, *send* and *receive*. *inparamdesc* is the input parameter descriptions illustrating how the registers and memory contents map to a list of parameters of interest(you might not care for all parameters) of a given function call while *outparamdesc* is the output parameter descriptions.

Table4.1 is an example of a function description. In this example, the function name is Read-File, it is a function for data receiving, so that function type is *receive*. The input parameter description has one concerned parameter, Handle while the output parameter description has two parameters, RecvBuffer and MessageLength. Handle is a parameter which is a value stored in the register RCX. The RecvBuffer is an address for the input message stored in the register RAX. The MessageLength is a output value stored in register R9. The value of the input parameters can be retrieved from the memory state on the function call instruction line while the value of the output parameters can be retrieved from the memory state on the function return instruction line. If a parameter is an address instead of value, the address should be retrieved first, then the retrieved address should be used to find the buffer content in the memory state. The function description requires the understanding of the calling convention of the operating system. The Microsoft x64 calling convention can be found in Appendix A. More examples of communication method descriptions will be given in Chapter5.

Input Parameter Description Output Parameter Description Name **Type** Name Register Addr/Val Name Register Addr/Val RecvBuffer **RDX** Addr ReadFile receive **RCX** Value Handle R9 Val MessageLength

Table 4.1: An example of a function description

4.3 Function Call Event Reconstruction Algorithm

In last two sections, I formalized the assembly execution trace and defined the function descriptor of a communication method. The function descriptor helps to locate the function calls and retrieve the parameters of interest from the execution trace. These function calls contain the information of a communication, such as the channel identifier, the packets send or received, etc. Before any communication can be identified, the function calls of that communication method have to be reconstruct first. In this section, I define the function call event and present the algorithm to reconstruct the function call events from the assembly execution trace.

With the function descriptor and the execution trace as input, the function call event reconstruc-

tion algorithm identifies function call entry instruction line and reconstruct the input parameters from the memory state of that line. Then it identifies the function call exit line of the corresponding function call and reconstruct the output parameters from the memory state of the function exit line. After iterate the whole execution trace, the algorithm outputs a sequence of function call events of size m which can be defined as:

```
etr = (ev_1, ev_2, ..., ev_m)
```

A function call event ev in etr is defined as a triplet:

```
ev = < funN, in params, outparams, type > \\
```

where funN is the function name, inparas includes all the input parameters with the parameter name and value while outparas includes all the output parameters, and type is the event type which inherit from the function description and can be one of the four types: open, send, receive and close.

Note: If the parameter is an address, the parameter's value is the string from the buffer pointed by that address instead of the buffer address.

An example of a sequence of function call events as the output of this algorithm is shown in Listing 4.1.

Listing 4.1: Example of *etr*

```
{funN:CreateNamedPipe, type:open,inparams:{Handler:18, FileName:mypipe}, outparams:{}},
{funN:CreateNamedPipe, type:open, inparams:{Handler:27, FileName:Apipe}, outparams:{}},
{funN:WriteFile, type:send, inparams:{Handler:27, SendBuf:Message1}, outparams:{MessageLen:9}},
{funN:WriteFile, type:send, inparams:{Handler:27, SendBuf:Message2}, outparams:{MessageLen:9}},
{funN:ReadFile, type:receive, inparams:{Handler:27}, outparams:{RecvBuf:Message3, MessageLen:9}},
{funN:CloseHandle, type:close, inparams:{Handler:27}, outparams:{}},
```

Algorithm 1 present the presudo code for the function call event reconstruction algorithm. This algorithm is designed to reconstruct the function call events of a communication method. If multiple communication methods are under investigated, this algorithm can be run multiple times to achieve the goal. Since the function descriptions usually contain a small number of functions compared to the instruction line number in the execution trace, the time complexity of this algorithm is O(N), N is the instruction line number of the trace.

Algorithm 1: Function Event Reconstruction Algorithm

```
/\star trace is the assembly execution trace with a sequence of instruction lines:
                                                                                                                     (l_1, l_2, ..., l_n),
       cdesc is the function descriptor contains a set of function descriptions:
       fdesc_1, fdesc_2, ..., fdesc_p, etr is a sequence of function call events
   Input: trace, cdesc
   Output: etr
\mathbf{2} \ etr \leftarrow \emptyset
   /* Emulate the Execute of each instruction line of the trace
4 while i \leq n do
        l \leftarrow trace[i]
        i \leftarrow i + 1
        Execute the instruction of l
        for fdesc \in cdesc do
              if l is a call to the function described by f des then
10
                   Create an new function call event ev
                   ev.funN \leftarrow fdesc.name
11
12
                   ev.type \leftarrow fdesc.type
13
                   Get the input parameters from the memory state and append them to ev.inparams
                   while i \leq n \ \mathrm{do}
14
                         l \leftarrow trace[i]
15
                         i \leftarrow i + 1
16
17
                         Execute the instruction of l
                         if l is a exit of the function described by f des then
18
                              Get the output parameters from the memory state and append them to ev.outparams
19
                              Break the inner while loop
20
                   etr.append(ev)
22 return etr
```

4.4 Channel Open Mechanisms

The channel open mechanism affect the stream identification and stream matching strategy. So I discuss them before presenting those algorithms. The channel open mechanism of named pipe and message queue is relatively simple. In windows implementation, only one function call is related to the handle identification of the stream. However, for TCP and UDP the mechanism is complicated.

In all communication methods, all operations such as packet send and receive use a handle as an identifier to bind itself to an endpoint. This handle is generated or returned by a channel open function call and will be assigned to an input parameter for all other related function calls to indicate the corresponding endpoint. However, in different communication, the handle might have various name, such as file handle for Named Pipe or socket(sometime called socket handle) for

UDP and TCP. But all of these are essentially the same thing.

A handle is a unique identifier among all open endpoints. Open endpoint means this endpoint is still in used for data transfer. For example, if there are ten endpoints opened for communications, handles for all these ten endpoints are different. However, if any of these endpoint closed, its handle can be reused for any other new created endpoints. Since the handle is the unique identifier for an endpoint and its related events, we need to know it to identify an endpoint and its corresponding function call events.

Moreover, since two endpoints are connected to a channel for communication, each endpoint has to know the identifier of the channel to connect to it. This channel identifier are usually given to the endpoint in the channel open function calls. The endpoint will remember this channel and know where the data should send to and receive from. Therefore, to identify a communication the channel identifier given to an endpoint need to be found in the channel open stage.

4.4.1 Named Pipe Channel Open Mechanisms

For Named Pipe communication method, a named pipe server is responsible for the creation of the pipe, while clients can connect to the pipe after it was created. The creation of a named pipe returns the file handle of that pipe. So the identification of the stream only need to identify the pipe creation function call on the server side and the pipe connection function call on the client side. The handle returned by these function calls will be used later when data is being sent or received to a specified pipe. In Named pipe, the file is used as the media of the channel, so the identifier in this case is the file name. Figure 4.4 exemplify the channel set up process for a Named Pipe communication in Windows.

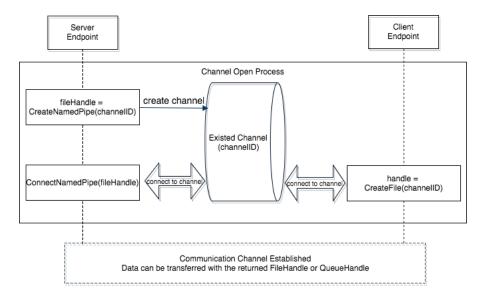

Figure 4.4: Channel Open Process for a Named Pipe in Windows

4.4.2 Message Queue Channel Open Mechanisms

For the Message Queue communication method, the endpoints of the communication can create the queue or use the existing one. However, both endpoints have to open the queue before they access it. The handle returned by the open queue function will be used later when messages are being sent or received to indicate the corresponding endpoint. The queue name as the input for the open queue function is the identifier of the channel. Figure 4.5 exemplify the channel set up process for a Message Queue communication in Windows.

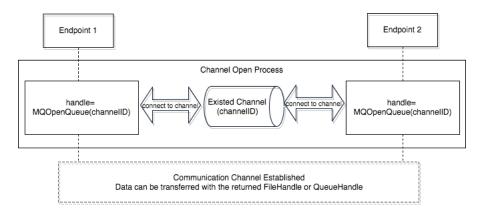

Figure 4.5: Channel Open Process for a Message Queue in Windows

4.4.3 UDP and TCP Channel Open Mechanisms

For UDP and TCP communication methods, the communication channel is set up by both endpoints of UDP and TCP channels. The function *socket* should be called to create their own socket on both endpoints. After the socket handles are created, the server endpoint binds the socket to its service address and port by calling the function *bind*. Then the server endpoint calls the function *accept* to accept the client connection. The client will call the function *connect* to connect to the server. When the function *accept* return successfully, a new socket handle will be generated and returned for further data transfer between the server endpoint and the connected client endpoint. After all these operations are performed successfully, the channel is established and the data transfer can start. During the channel open stage, server endpoint has two socket handles, the first one is used to listen to the connection from the client, while the second one is created for real data transfer. The server's address and port in this case are considered to be the identifier of the channel. Figure 4.6 exemplify the channel open process for TCP and UDP in Windows.

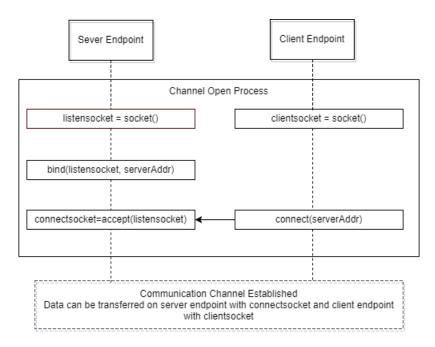

Figure 4.6: Channel Open Model for TCP and UDP in Windows

4.5 Stream Extraction Algorithm

The sequence of function call events output by the function call event reconstruction algorithm may belong to different endpoint. We need to further split them for different endpoints. Each subset of this events belong to an endpoint was considered to be a stream. There are four types of events in each of these subsets: open, send, receive and close. Hence, we can further divide a stream into sub streams which can be called open stream, send stream, receive stream, and close stream. There will be only one type of events in each type of these stream. Since a stream is corresponding to an endpoint and an endpoint is connected to a channel, it is useful to have the endpoint handle and the channel identification when referring to this stream.

A stream is formally defined as a tuple:

```
s = \langle handle, channelId, so, ss, sr, sc \rangle
```

where handle is the handle of the endpoint, channelId is the identifier of the channel the endpoint of this stream is connected to, so is the open stream, ss is the send stream, sr is the receive stream, sc is the close stream.

The sub streams: so, ss, sr, sc are sequences of events, each sub stream sx is defined as:

```
sx = (ev_1, ev_2, ..., ev_p)
```

Note: The event numbering of in this sub streams is different from the original sequence of event. For example, ev_1 in s and ev_1 in etr might be different events.

the stream extraction algorithm is designed to extract the streams from the sequence of function call events. In this algorithm, the stream is need to be identified by the endpoint handle output by channel open function calls first. Then all other events will be added to the stream. According to the channel open mechanisms discussed in Section4.4, the identifier of the channel and the handle of the endpoint can be retrieved from the channel open function call events.

The input of this algorithm is the sequence of events $etr = (ev_1, ev_2, ..., ev_n)$ from the function event reconstruction algorithm. Since the events in etr are reconstructed in sequence of the instructions which are order by the time of occurrence, the events are implicitly sorted by time of occurrence.

The output of this algorithm is a set of stream of size p, which can be defined as:

$$str = (s_1, s_2, ..., s_p)$$

According to the channel open mechanisms, two different algorithms are designed, one is for Name pipe and Message Queue, while the other is for TCP and UDP.

Stream Extraction Algorithm for Named Pipe and Message Queue

This algorithm is designed for extraction of the streams for Named Pipe and Message Queue. Since for each endpoint of the communication, only one channel open function call is needed to identify the endpoint, it is simple to identify the stream once channel open function call event that create the endpoint handle is found.

The same handle may be reused by other endpoint. However, reuse of the handle would not happen before this stream was closed by the channel close function call event. Therefore, before the detection of the channel close function call, if a new channel open function call with the same returned handle is detected, the second channel open will be ignored. This algorithm handle this by having the temperate set tempstreams to keep track of the streams that are still open. Once the stream was closed, the handle can be used by another stream. The time complexity of this algorithm is O(N), N is the number of events in the trace.

Algorithm 2: Stream Extraction Algorithm for Named Pipe and Message Queue

```
/\star etr is a sequence of function call events output by Algorithm 1; str is a set of streams
        corresponding to a set of endpoints
   Input: etr
   Output: str
1 str \leftarrow \emptyset
   /* a temperate stream set for all open streams
2 tempstreams \leftarrow \emptyset
\mathbf{3} \ \mathbf{ for } \, ev \in etr \, \mathbf{do}
        if ev.type = open then
              h \gets \text{the handle in } ev.outparams
              if tempstreams[h] not exist then
 6
 7
                    tempstreams[h] \leftarrow a \text{ new } s
 8
                    tempstreams[h].handle \leftarrow h
                    tempstreams[h].channelId \leftarrow \text{the channel identifier from } ev.inparams
                    tempstreams[h].so.append(ev) \\
10
         else if ev.type = send then
              h \gets \text{the handle in } ev.inparams
12
              if tempstreams[h] exist then
13
                   tempstreams[h].ss.append(ev) \\
14
         else if ev.type = receive then
15
16
              h \gets \text{the handle in } ev.inparams
              if tempstreams[h] exist then
                   tempstreams[h].sr.append(ev)
18
         else if ev.type = close then
19
20
              h \leftarrow \text{the handle in } ev.inparams
21
              if tempstreams[h] exist then
                    tempstreams[h].sc.append(ev)
22
                    str.append(tempstreams[h])
23
                    remove tempstreams[h] from tempstreams
24
25
         else
              unknown event type error
27 return str
```

Stream Extraction Algorithm for TCP and UDP

This algorithm is designed for extraction of the streams for TCP and UDP. In the channel open stage, socket handles are created by function calls of *socket* in both client and server. In the server side, this created socket is only used for listening to the client's connection. The listening is accomplished by calling the function *accept*. One of the input parameters of the *accept* function call is the listening socket handle, and the output of it is a new data transmission socket handle.

In this algorithm, each created socket will be identified as a stream. So that the two socket handles in the server side are considered to be two handles for two streams, the stream identified by the listening handle is called the parent stream and the one identified by the data transmission handle is called the child stream. However the events in the parents stream contain the information needed for stream matching algorithm later, so the children stream will inherit all the events from their parents.

Same as the algorithm for Named pipe and Message Queue, the reused of a handle can only happen after a stream identified by this handle is closed. Otherwise the handle reuse will be treated as an error. A temperate set *tempstreams* is also used in this algorithm to keep check of the open streams.

The time complexity of this algorithm is also O(N), N is the number of events in the trace.

Algorithm 3: Stream Exatraction Algorithm for TCP and UDP

```
/\star etr is a sequence of function call events output by Algorithm 1; str is a sequence of
       streams corresponding
   Input: etr
   Output: str
1 str \leftarrow \emptyset;
   /* a temperate stream set for all open streams
2 tempstreams \leftarrow \emptyset;
3 for ev \in etr do
        if ev.funN = socket then
             h \leftarrow \text{the handle in } ev.outparams;
             if tempstreams[h] not exist then
                   tempstreams[h] \leftarrow \texttt{a new } s
                                                                              // new a stream;
                   tempstreams[h].handle \leftarrow h;
 8
                   tempstreams[h].so.append(ev);
        else if ev.funN = bind \ or \ ev.funN = connect then
10
             h \leftarrow \text{the handle in } ev.inparams;
11
             if tempstreams[h] exist then
12
                   tempstreams[h].channelId \leftarrow address and port parameter in ev.inparams;
13
                   tempstreams[h].so.append(ev);
14
        else if ev.funN = accept then
15
             h \leftarrow \text{the handle in } ev.inparams;
                                                                  // the handle of parent stream;
17
             hc \leftarrow \text{the handle in } ev.outparams;
                                                                    // the handle of child stream;
             if tempstreams[h] exist then
18
                   if tempstreams[hc] not exist then
19
                    tempstreams[hc] \leftarrow a \text{ new } s;
                                                                       // a new stream for the child;
20
                   tempstreams[hc].handle \leftarrow hc;
21
                   tempstreams[hc].channelId \leftarrow tempstreams[h].channelId;
22
                   tempstreams[hc].so.append(tempstreams[h]);
                                                                                  // append parent's events;
23
                   tempstreams[hc].so.append(ev);
                                                                         // append the current event;
24
        else if ev.type = send then
             h \leftarrow \text{the handle in } ev.inparams;
26
27
             if tempstreams[h] exist then
                  tempstreams [h].ss.append (ev);\\
28
        else if ev.type = receive then
29
             h \leftarrow \text{the handle in } ev.inparams;
30
31
             if tempstreams[h] exist then
                  tempstreams[h].sr.append(ev);
32
        else if ev.type = close then
33
34
             h \leftarrow the handle identifier from ev.paras;
             if tempstreams[h] exist then
35
                   tempstreams [h]. sc. append (ev);\\
                   str.append(tempstreams[h]);
37
                   remove tempstreams[h] from tempstreams;
38
        else
             unknown event type or name error;
41 return str;
```

4.6 Stream Matching Algorithm

The function event extraction algorithm and the stream extraction algorithms all work on a single execution trace. As defined before a communication has two endpoint and each endpoint corresponds to a stream. So that, to identify a communication from the dual_trace, the two streams of that communication need to be found.

The stream matching algorithm iterate all the streams extracted from both traces of a dual_trace and try two match one stream of a trace to the other stream of another trace by the channel identifier held by each stream.

The channel identifier held by each stream is extracted with the stream in the stream extraction algorithm and is different from communication method to communication method. For TCP and UDP channel identifier is server's address and port. so the matching can be considered as local address and port of server endpoint matching with remote address and port of client endpoint. For Named Pipe, the channel identifier is the file name while for Message Queue, the channel identifier is the the queue name.

The inputs of this algorithm are two sequence of streams str_0 and str_1 which are output by the stream extraction algorithm. The output of this algorithm is a sequence of the preliminary communications cs of the matched streams. Each matched item in it is a triple $< channel Id, s_0, s_1 >$, where channel is the identifier of the channel, while s_0 and s_0 are the streams from $trace_0$ and $trace_1$. The time complexity of this algorithm is O(N*M), N and M are the number of streams in both traces.

Algorithm 4: Stream Matching Algorithm for Named Pipe and Message Queue

This matching algorithm is not fully reliable. There are two situations which the matching will be errors. Take Named Pipe for example, the first situation is multiple(more than two) interacting programs shared the same file as their own channel. Even though the channels are distinct for each communication, but the file is the same one. For example, the Named Pipe server is connected by two clients using the same file. In the server trace, there are two streams found. In each client

trace, there is one stream found. For the dual_trace of server and client1, there will be two possible identified communications, one is the real communication for server and client1 while the other is an error which actually is for server and client2. The stream in client1's trace will be matched by two streams in the server's trace. The second situation is the same channel is reused by the different endpoints in the same programs. For example, the Named Pipe server and client finished the first communication and then closed the channel. After a while they re-open the same file again for another communication. The matching is based on the identifiers. So that in this case, there will be two matching. Similar situations can also happen in Message Queue, TCP and UDP communication methods. The data stream verification algorithm discussed in next section can reduce these errors.

4.7 Data Stream Verification Algorithm

In last section, I present the simply stream matching algorithm and describe the situations in which the matching can go wrong. In this section, I present the algorithm that I designed to verify if the data in the streams of the preliminary identified communication satisfy the communication preservations of the communication model in Chapter 3.

The data transfer characteristics divided the communications into reliable and unreliable categories. Named Pipe and TCP fall in the reliable category while Message Queue and UDP fall in the unreliable one. The properties of the models consists of content preservation and timing preservation. So that the verification should cover both preservations:

- verify the content preservation of the data in the matched streams.
- verify the timing preservation of the data in the matched streams.

To verify the timing preservation, the relative time of the events in both streams is needed. Unfortunately, we can only determine the relative time with in a stream but not crossing two streams. So that it's infeasible to verify the timing preservations no matter for reliable or unreliable communications. The verification algorithms discussed in this section will only cover the content preservation.

The inputs of the data stream verification algorithms are two preliminary matched streams s_0 and s_1 . The output is the a boolean indicating if the streams satisfy the content preservation. All communications don't satisfy the content preservation should be excluded.

For each communication method the verification of the corresponding preservation is applied, That is, for Named Pipe and TCP, the reliable communication preservation need to be verified and for Message Queue and UDP, the unreliable communication preservation need to be verified. The following sub sections present the versification algorithms for these four communication methods. In each sub section, I discuss the data transfer properties and scenarios of the communication method and then present the developed verification algorithm.

4.7.1 Data Stream Verification Algorithm for Named Pipe

A named pipe provides FIFO communication mechanism for inter-process communication. It can be a one-way or a duplex pipe. [13]

The basic data transfer characteristics of Named Pipe are:

- Bytes are received in order
- Bytes sent as a segment can be received in multiple segments(the opposite is not true)
- No data duplication
- If a sent segment is loss, all the following segments will lost(this happen when the receiver disconnect from the channel)

Based on these characteristics, the data transfer scenarios of Named pipe can be exemplified in Figure 4.7.

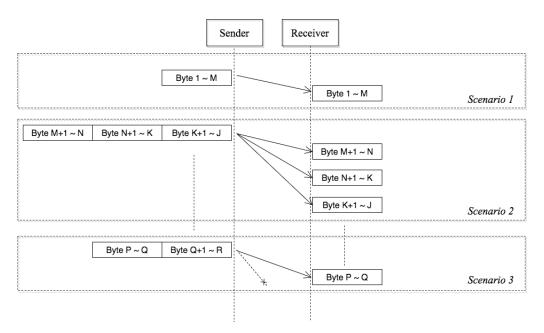

Figure 4.7: Data Transfer Scenarios for Named Pipe

The content preservation verification is trivial as comparing the concatenation of the packet content of the sent events in a stream to the the concatenation of the packet content of the receive events in the other stream, which is presented in Algorithm 4.6. Since the concatenation need to go through the events in the streams, the time complexity of this algorithm is also O(N), N is the total number of data transfer events in the two streams.

Algorithm 5: Data Stream Verification of Named Pipe

4.7.2 Data Stream Verification Algorithm for TCP

TCP is the most fundamental reliable transport method in computer networking. TCP provides reliable, ordered, and error-checked delivery of a stream of octets between applications running on hosts in an IP network. The TCP header contains the sequence number of the sending octets and the acknowledge sequence this endpoint is expecting from the other endpoint(if ACK is set). The re-transmission mechanism is based on the ACK.

The basic data transfer characteristics of TCP are:

- Bytes received in order
- No data lost(lost data will be re-transmitted)
- No data duplication
- Bytes sent in packet and received in packet, no re-segmentation

Based on these characteristics, the data transfer scenarios of TCP can be exemplified in Figure 4.8.

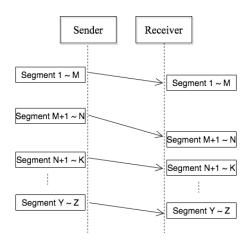

Figure 4.8: Data Transfer Scenarios for TCP

Regrading to the data transfer properties of TCP, the verification can be restricted to packet to packet. If all the send and receive events of the two streams can be matched, we can assert that the content preservation are satisfied. The verification algorithm of TCP is presented in Algorithm 6. The time complexity of this algorithm is also O(N), N is the number of data transfer events in a stream.

Algorithm 6: Data Stream Verification of TCP

```
Input: s_0, s_1

1 return satisfied

2 if s_0.ss.size! = s_1.sr.size \ Or \ s_1.ss.size! = s_0..sr.size then

3 \[
\begin{align*} \text{return False}; \\
4 \text{ for } i \in 0..s_0.ss.size \text{ do} \\
5 \[
\begin{align*} \text{if } s_0.ss[i].payload! = s_1.sr[i].payload \text{ then} \\
6 \[
\begin{align*} \text{return False}; \\
7 \text{ for } i \in 0..s_1.ss.size \text{ do} \\
8 \[
\begin{align*} \text{if } s_1.ss[i].payload! = s_0.sr[i].payload \text{ then} \\
9 \[
\begin{align*} \text{trurn False}; \\
10 \text{ return True}; \end{align*}
```

4.7.3 Data Stream Verification Algorithm for Message Queue

Message Queuing is a communication method to allow applications which are running at different times across heterogeneous networks and systems that may be temporarily offline can still communicate with each other. Messages are sent to and read from queues by applications. Multiple sending applications can send messages to and multiple receiving applications can read messages from one queue.[17] In this work, only one sending application versus one receiving application case is considered. Multiple senders to multiple receivers scenario can be divided into multiple

sender and receiver situation. Both applications of a communication can send to and receive from the channel.

The basic data transfer characteristics of Message Queue are:

- Bytes sent in packet and received in packet, no bytes re-segmented
- Packets can lost
- Packets received in order
- No data duplication

Based on these characteristics, the data transfer scenarios of Message Queue can be exemplified in Figure 4.9.

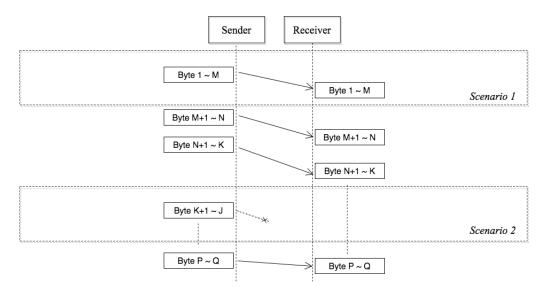

Figure 4.9: Data Transfer Scenarios for Message Queue

To verify the content preservation of the unreliable communication, Algorithm 7 tries to find the match sent packet in the other stream for each received packet. If any of the received packet can not be match, the content preservation is not satisfied. Since the sent packets are received in order, the searching for each received packet will start from the next index of the last matching sent packet.

The time complexity of this algorithm is $O(N^2 + M^2)$, N and M are the numbers of data sent events of the two streams.

Algorithm 7: Data Stream Verification of Message Queue

```
Input: s_0, s_1
1 return satisfied
2 if s_0.ss.size < s_1.sr.size Or s_1.ss.size < s_0.sr.size then
        return False;
4 lastMatchIndex = 0;
5 for i \in 0..s_1.sr.size do
        tempIndex = lastMatchIndex;
        for j \in lastMatchIndex + 1..s_0.ss.size do
              if s_0.ss[j].payload = s_1[i].sr.payload then
                   lastMatchIndex \leftarrow j;
                   break the inner For loop;
10
         /* This received packet can not be matched by any sent packet
        \label{eq:continuous_def} \textbf{if} \ tempIndex = lastMatchIndex \ \textbf{then}
11
              return False;
12
13 lastMatchIndex = 0;
14 for i \in 0...s_0.sr.size do
        tempIndex = lastMatchIndex;
        for j \in lastMatchIndex + 1..sends_1.size do
              if s_1.ss[j].payload = s_0[i].sr.payload then
17
                   lastMatchIndex \leftarrow j;
18
                   break the inner For loop;
19
20
        if tempIndex = lastMatchIndex then
              return False;
22 return True:
```

4.7.4 Data Stream Verification Algorithm for UDP

UDP is a widely used unreliable transmission method in computer networking. It is a simple protocol mechanism, which has no guarantee of delivery, ordering, or duplicate protection. This transmission method is suitable for many real time systems.

The basic data transfer characteristics of UDP are:

- Bytes sent in packet and received in packet, no re-segmentation
- Packets can lost
- Packets can be duplicated
- Packets can arrive receiver out of order

Based on these characteristics, the data transfer scenarios of UDP can be exemplified in Figure 4.10.

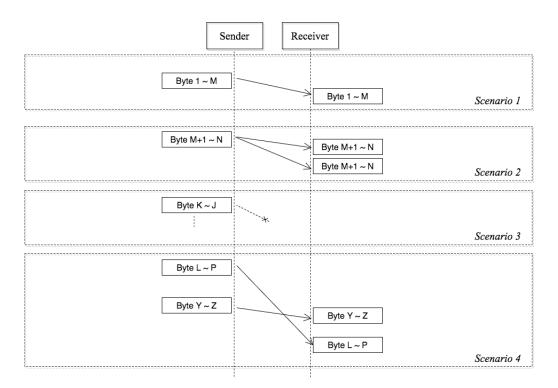

Figure 4.10: Data Transfer Scenarios for UDP

Similar to Message Queue, Algorithm 8 try to find the match sent packet in the other stream for each received packet. If any of the received packet can not be match, the content preservation is not satisfied. However, due to the disordering can happen in UDP, the searching for each received packet will not constraint the searching index. But the matched sent packet will excluded from the following searching, which means each sent packet can only match to one received packet.

The time complexity of this algorithm is $O(N^2 + M^2)$, N and M are the numbers of data sent transfer events in the two streams.

Algorithm 8: Transmitted Verification of UDP

```
Input: s_0, s_1
1 return satisfied
2 if s_0.ss.size < s_1.sr.size Or s_1.ss.size < s_0.sr.size then
        return False;
4 for i \in 0..s_1.sr.size do
        matchFlag = False;
        for j \in 0..s_0.ss.size do
             if s_0[j].ss.payload = s_1[i].sr.payload then
 8
                  matchFlag = True;
                  delete the packet from sends_0 break the inner For loop;
        /* This received packet can not be matched by any sent packet
        if matchFlag = False then
10
             return False;
11
12 for i \in 0..s_0.sr.size do
        matchFlag = False;
13
        for j \in 0..s_1.ss.size do
14
             if s_1[j].ss.payload = s_0[i].sr.payload then
15
                  matchFlag = True;
16
                  delete the packet from s_0.ss break the inner For loop;
17
        if matchFlag = False then
18
             return False;
20 return True;
```

4.7.5 Limitation of the Verification

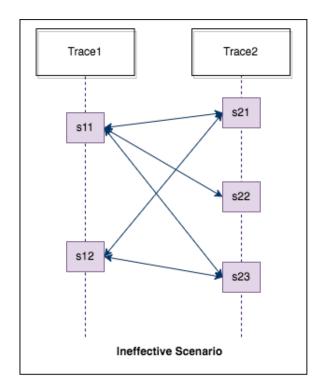

The Identification discussed in this chapter is not perfect. It has two major limitations:

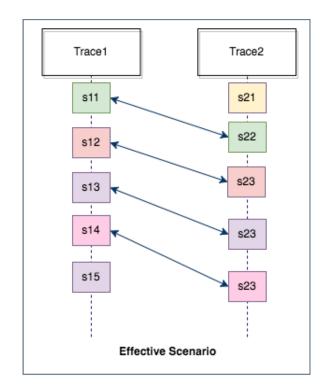

- The timing preservation of the communication is not verified.
- Due to the data transmitted in two communications can be identical(or their difference can not be tell by the content verification). In this cases, one stream in one side of the dual_trace can be matched by two or more streams on the other side. Figure 4.11 indicates the ineffective and effective stream matching scenarios even with the content verification.

In the Ineffective Scenario shown in Figure 4.11, s_{11} are matched with s_{21} , s_{22} and s_{23} in the stream matching algorithm. So data stream verification algorithm will apply on (s_{11}, s_{21}) , (s_{11}, s_{22}) and (s_{11}, s_{23}) . In this case, all of them are considered to satisfy the content preservation by this algorithm, so this three streams pairs are all identified as a valid communication, even through that is not true. Same as (s_{12}, s_{21}) , (s_{12}, s_{22}) and (s_{12}, s_{23}) . There is no way from the analysis point of view to distinct the actual communication and exclude the invalid ones. I conserve all of them in the output and present them to the users to make the

decision. With assistant information, the users might be able to distinguish them and find the valid one.

In the effective scenario, one stream in one side of the dual_trace is only matched with one stream on the other side, which is ideal from the analysis point of view.

Stream, the filled color represent the transmitted data of the stream, if the data is considered to be identical the color will the exactly the same otherwise they are different

Streams Matched and Communication Identified

Figure 4.11: Stream Matching Scenarios

Chapter 5

Feature Prototype On Atlantis

In this chapter, I present the design of the feature prototype of communication identification from the dual_trace. This prototype implemented some of the algorithms described in Chapter4 as well as the user interfaces.

This feature is implemented on Atlantis to utilize its other features, such as "memory reconstruction", "function inspect" and "views synchronization". Figure 4.3 shows the decoded information needed to identify a function call of interest from the trace. The feature "function inspect" of Atlantis provide this decoding functionality. In the function call event reconstruction algorithm, the parameters of a function call is are retrieved from the memory state, the "memory reconstruction" functionality of Atlantis which compute the memory state of the instruction line efficiently makes this retrieval easier. Moreover, the "views synchronization" ability of Atlantis benefit the user when they are navigating and viewing the communication identification result.

This prototype consists of four components: 1) user setting for the function descriptors of the communication methods. 2) a view that can parallel display both traces in the dual_trace. 3) two features: stream extraction and communication identification. 4) stream extraction or communication identification result navigation.

To analyse a dual_trace, the user need to 1) open two traces in the parallel editor(developed in this prototype), 2) import the dynamic linked library file for each trace(existing feature of Atlantis), 3) perform the stream extraction or communication identification operations(developed in this prototype), and finally 4) inspect the operation results(by the operation menu developed in this prototype and the navigation functions existing in Atlantis).

Before describing the detail of each of these component, I provide two use cases corresponding to the two main features: stream extraction and communication identification of this prototype as shown in Table 5.1 and Table 5.2.

Table 5.1: Use Case 1: Extract Streams from the Dual_trace

Name	Analysis streams of a communication method from the Dual_trace									
Description	A user captured two assembly execution traces of two interacting program									
	and need to analysis them by extracting all communication streams of each of									
	the traces and inspecting the extraction results									
Actor	A Software Security Engineer									
Precondition	The user has two assembly execution trace and the .dll files on the systems									
	where the programs of the captured traces were running									
Main Course	1. The user input the function descriptor for the communication methods of									
	interest to the Json format setting file									
	2. The user open one of the trace in Atlantis									
	3. The user open the other trace as the dual_trace of the first one									
	4. The two opened traces are presented in the parallel editor view									
	5. The user load the related .dll files which contains the information of the									
	functions in the function descriptors for both opened trace									
	6. The user select the operation "Stream Extraction" in the "Dual_Trace Tool"									
	menu.									
	7. Atlantis prompt a dialogue window giving the user all the communication									
	methods in the function descriptor setting file as option									
	8. The user select the communication methods which they want to analyse									
	and click the "OK" bottom									
	9. Atlantis extract the streams for both traces and list the result in "Commu-									
	nication view"									
	10. The user expand the result in the "Communication view"									
	11. The user select one function call event in a stream and double click the									
	entry									
	12. Atlantis navigation to the corresponding instruction line in the trace and									
	synchronize all other views									

Table 5.2: Use Case 2: Identify Communications from the Dual_trace

Name	Analysis communications of a communication method from the Dual_trace									
Description	A user captured two assembly execution traces of two interacting program									
	and need to analysis them by identify all communications of the dual_trace									
	and inspecting the extraction results

	entry									
	12. Atlantis navigation to the corresponding instruction line in the trace and									
	synchronize all other views									

5.1 User Setting of the Function Descriptors

In Section 4.2, I defined a function descriptor as a set of function descriptions for a communication method. The communication identification approach can identify the communications described

by the function descriptor from the dual_trace.

However, the communication method description for a communication method can be different depends on the implementation solution of the communication method. Furthermore, there are so many communication methods in the real world, it is impossible to pre-define all of them for the users. Instead, a configuration file in Json format is provided for the users to define their communication methods of interest and the corresponding function descriptors. A default template is given for user reference, this default template is generated by Atlantis when it was launched and stored in the .tmp folder in the trace analysis project folder. The users can modify this template as to the communication methods of interest. The default template example can be find in SectionB.

The function descriptors in this setting file will be the input for the stream extraction and communication identification features. When the user use this two features, the list of the communication methods provided in the setting files will be presented to them. They can select one or more communication methods to be analysed.

In the following subsections, function descriptor examples are presented as user reference to how to design their own function descriptor for a communication method.

5.1.1 Communication Methods' Implementation in Windows

Learning the implementation of a communication is necessary to obtain the function descriptor of the communication method. In this section, I present the result of investigation about the implementation of the four communication methods: Named Pipe, Message Queue, TCP and UDP in Windows. In the investigation, I reviewed the Windows APIs of the communication methods and their example code. By doing so, I obtained the function descriptors of these methods can be designed by this investigation.

Windows API set is very sophisticated. Moreover, multiple solutions are provided to fulfil a communication method. It is impossible to enumerate all solutions for each communication method. I only investigated the most basic usage provided in Windows documentation. For each communication method, a function descriptor with a list of system function descriptions is provided for reference. The functions in the descriptors are supported in most Windows operating systems, such as Windows 8, Window 7. The provided function descriptor of a communication method should only be considered as an example for that communication method. With the understanding of this, it should be fairly easy to obtain the function descriptors for other solutions of that communication method or other communication methods.

Note that, the instances of the descriptors only demonstrate Windows C++ APIs. But the idea of the function descriptor is generalizable to other operating systems with the effort of understanding

the APIs of those operating systems.

Windows Calling Convention

The Windows calling convention is important to know in this research. The communication identification from dual_trace in assembly level relies not only on the system function names but also the key parameter values. In the assembly level execution traces, the parameter values is captured in the memory changes and register changes of the instructions but without any information indicating which registers or memory addresses are holding this parameters. The calling convention tells us where the parameters are stored. So that we can find them in the memory state while emulate the execution of the trace. Calling Convention is various for operating systems and the programming language. I used dual-trace of Microsoft* x64 programs for case study in this research. The Microsoft* x64 example calling convention is listed in Appendix A.

Named Pipes

In Windows, a named pipe is a communication method for the pipe server and one or more pipe clients. The pipe has a name, can be one-way or duplex. Both the server and clients can read or write into the pipe.[15] In this work, I only consider one server versus one client communication. One server to multiple clients scenario can always be divided into multiple server and client communications thanks to the characteristic that each client and server communication has a separate conduit. The server and client are endpoints in the communication. We call the server "server endpoint" while the client "client endpoint". The server endpoint and client endpoint of a named pipe share the same pipe name, but each endpoint has its own buffers and handles.

There are two modes for data transfer in the named pipe communication method, synchronous and asynchronous. Modes affect the functions used to complete the send and receive operation. Both descriptors for both synchronous mode and asynchronous mode are provided. The create channel functions for both modes are the same but with different input parameter value. The functions for send and receive message are also the same for both cases. However, the operation of the send and receive functions are different for different modes. In addition, an extra function *GetOverlappedResult* is being called to check if the sending or receiving operation finish, the output message will be stored in the overlap structure whose memory address saved in the function's output parameter Overlap Structure Address. Table 5.3 is the function descriptor for synchronous mode while Table 5.4 is the function descriptor asynchronous mode of Named pipe.

Table 5.3: Function Descriptor for Synchronous Named Pipe

Name	Tyme	Input Parameter Description			Output Parameter Description		
Name	Type	Name	Register	Addr/Val	Name	Register	Addr/Val
CreateNamedPipe	open	FileName	RCX	Addr	Handle	RAX	Val
CreateFile	open	FileName	RCX	Addr	Handle	RAX	Val

CreateFile	open	FileName	RCX	Addr	Handle	RAX	Val
WriteFile	send	Handle	RCX	Val	Lanath	R9	Val
		SendBuf	RDX	Addr	Length		vai
ReadFile	receive	Handle	RCX	Val	Lanath	R9	Val
Reaurile		RecvBuf	RDX	Addr	Length		
GetOverlappedResult	receive	Handle	RCX	Val	OverlapStruct	RDX	Addr
CloseHandle	close	Handle	RCX	Val			
DisconnectNamedPipe	close	Handle	RCX	Val			

Message Queue

Similar to Named Pipe, Message Queue's implementation in Windows also has two modes, synchronous and asynchronous. Moreover, the asynchronous mode further divides into two operations, one with callback function while the other without. With the callback function, the callback function would be called when the send or receive operations finish. Without callback function, the general function MQGetOverlappedResult should be called by the endpoints to check if the message sending or receiving operation finish, the parameter in RCX of this function call is a

structure consist of the handle as an input parameter and the overlap structure as an output parameter. Table 5.5 is the function descriptor for synchronous mode while Table 5.6 is the function descriptor for the asynchronous mode without callback. With callback function situation is not elaborated here.

Table 5.5: Function Descriptor for Synchronous Message Queue

Nama	Туре	Input Para	ameter Des	cription	Output Parameter Description		
Name		Name	Register	Addr/Val	Name	Register	Addr/Val

MQCloseQueue	close	Handle	RCX	Val			

TCP and UDP

In Windows programming, these two methods shared the same set of APIs regardless the input parameter values and operation behaviour are different. In Windows socket solution, one of the two endpoints is the server while the other one is the client. Table 5.7 is the function descriptor for UDP or TCP communication.

Table 5.7: Function Descriptor for TCP and UDP

Name	Туре	Input Para	ameter Des	cription	Output Parameter Description

5.2 Parallel Editor View For Dual_Trace

The dual_trace consist of two execution traces which are interacting with each other. Presenting them in the same view makes the analysis for the user much easier. To open parallel editor view, the user need to open one trace as the normal one and the other as the dual_trace of the opened one. A new menu option in the project navigation view are added to open the second trace as the dual_trace of the active trace. The implementation of the parallel editor take the advantage of the existing SWT of Eclipse plug-in development. The detail of the implementation can be found in Appendix C. Figure 5.1 shows this menu option and Figure C shows the parallel editor view.

Figure 5.2: Parallel Editor View

5.3 Features

I implemented two features. The first one is stream extraction corresponding to the stream extraction algorithm presented in Chapter4 for both traces in the dual_trace. The other one is the communication identification corresponding to the overall communication process discussed in Chapter4. The implementation of these two features relies on the existing "function inspect" feature of Atlantis. The called functions' name can be inspected by search of the symbolic name in the executable binary or any DLLs which used by the program at the time when it is traced. By importing the DLLs and executable binary, Atlantis can recognize the function call from the execution trace by the function names. Therefore the corresponding Dlls or executable binaries for both traces in the dual_trace have to be loaded into Atlantis before conducting the identification.

A new menu "Dual_trace Tool" with three menu options is designed for these two features. In this menu, "Stream Extraction" is for the operation of stream extraction and "Communication Identification" is for the operation of communication identification. For both of these two operation "Load Library Exports" has to be run before for both traces. Currently, the "Load library export"

operation can only load libraries for the trace in the active editor. So "Load library export" in the menu has to be run twice separately for each trace of the dual_trace. Figure 5.3 shows this new menu in Atlantis. When the user perform "Stream Extraction" or "Communication Identification", there will be a prompt dialog as shown in Figure 5.4 which asks the user what communication methods they want to analyse from the dual_trace. This list is provided by the configuration file I mention in Section 5.1. The user can select one or multiple methods.

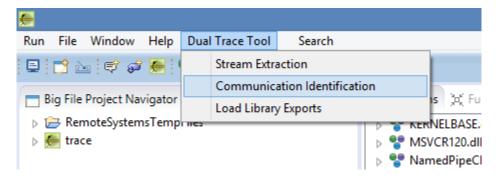

Figure 5.3: Dual_trace Tool Menu

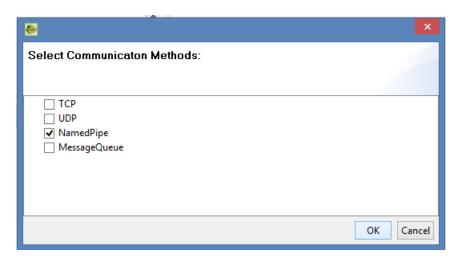

Figure 5.4: Prompt Dialog for Communication Selection

A new view named "Communication" is designed for presenting the result of the extracted streams and the identified communications. Since the user can have multiple selection for communication methods of interest, the output identification result contains all the identified communications or streams of all selected communication methods and the results are clustered by methods. There are two sub tables in this view, the left one is for presenting the extracted the streams result while the left one is for presenting communication identification result. The reason for putting this

two result in the same view is for easy access and comparison of the data for the users. Figure 5.5 shows this view with result data in it. Each time when the user rerun the features the result in the corresponding table will be refreshed to show only the latest identification result. But the other table will not be affected. For example, if the user run the "Stream Extraction" feature first, the stream result will show on the left table of the view. And then the user run the "communication Identification", the communication identification result will be shown on the right table while the left one still holding the last stream result.

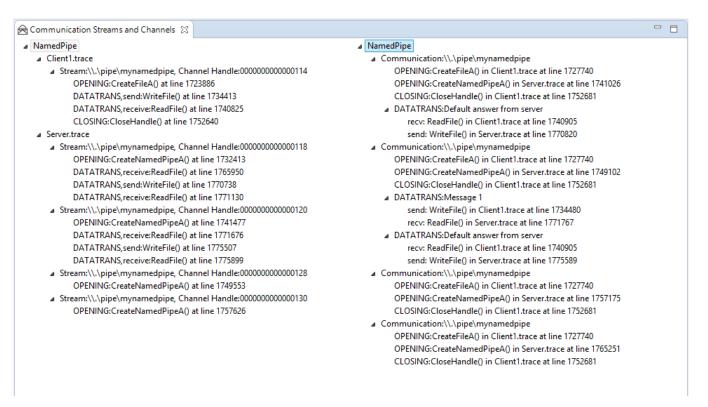

Figure 5.5: Communication View for Result

5.4 Result Navigation

Atlantis is a analysis environment that has various views to allow user access to different information from the trace, such as the memory and register state of the current instruction line. Moreover, these views synchronize automatically with the editor view. These functionality and information also benefit the communication analysis of the dual_trace. Providing the user a way to navigate from the result to the traces in the editors allows them to take advantage of the current existing functionality of Atlantis and make their analysis of the dual_trace more efficient.

In the result list, each event entry is corresponding to a function call. The functions were called at function call line and all the inputs of the function calls can be recovered from the memory state of this instruction line. The functions returned at the return instruction lines, all the outputs of the function calls can be recovered in the memory state of the the return instruction line. From the event entries, this implementation provide two different ways for the user to navigate back to where the function begins and ends. When the user "double click" on an entry, it will bring the user to the start line of the function in the corresponding trace editor. When the the right click on the event entry, a prompted menu with the option "Go To Line of Function End" will show up as in Figure 5.6. Clicking on this option will bring the user to the return line of this function in the trace editor. All other views update immediately with this navigation.

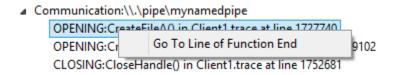

Figure 5.6: Right Click Menu on Event Entry

Moreover, the "remove" option as shown in Figure 5.7 in the right click menu on the "stream or "communication" entries is provided for the user to remove the selected "stream" or "communication" entry. This provides the user the flexibility to get rid of the data that they don't care.

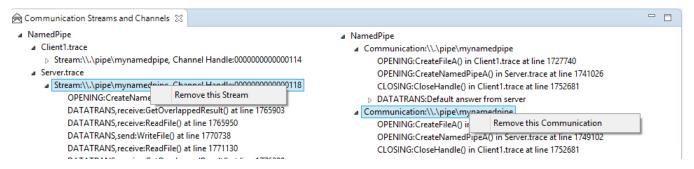

Figure 5.7: Right Click Menu on Event Entry

Chapter 6

Proof of Concept

In this section, I present two experiments I ran for the proof of concept of the communication analysis though execution traces.

These experiments aimed to test the communication model and the communication identification approach. They also verify the design of the some algorithms, for their correctness.

User case study is not included in this thesis and can be the future work. The feature prototype implementation is not evaluated and can be part of the user case study. But I used the implemented feature on Atlantis to conduct the experiments.

I first present the design of the experiments and their result. And then, I discuss the result of the experiments.

Among the two experiments, the first simpler one was provided directly by DRDC with their initial requirement, while the second one was designed by me. In both experiments, DRDC conducted the program execution and trace capture on their environment while I performed the analysis locally with Atlantis on my desktop with the captured traces and corresponding .dll.

6.1 Experiments

In this section, I describe the design of the experiments. Two experiments are conducted in this research. All test programs in these two experiments were written in C++ and the source code can be found in Appendix D. Our research partner DRDC executed the programs in their environment and provided the captured traces, the used .dll files and the source code of the programs for the experiments.

Results are provided for each experiment. Both of the conducted experiments were about named pipe communication method. The following two subsections provides the details of the

6.1.1 Experiment 1

In the first experiment, two programs communicated with each other through a synchronous Named pipe channel. One of the programs acted as the Named pipe server while the other as the client. Figure 6.1 is the sequence diagram of the interaction between the server and client. Traces were captured while these two program were running and interacting. The two captured traces were analysed as dual_trace exp1 in this experiment. I used the implemented features in Atlantis to analyse this dual_trace. I ran the "Stream identification" and "Communication identification" operations for this dual_trace. The streams and communication are showed in Figure 6.2.

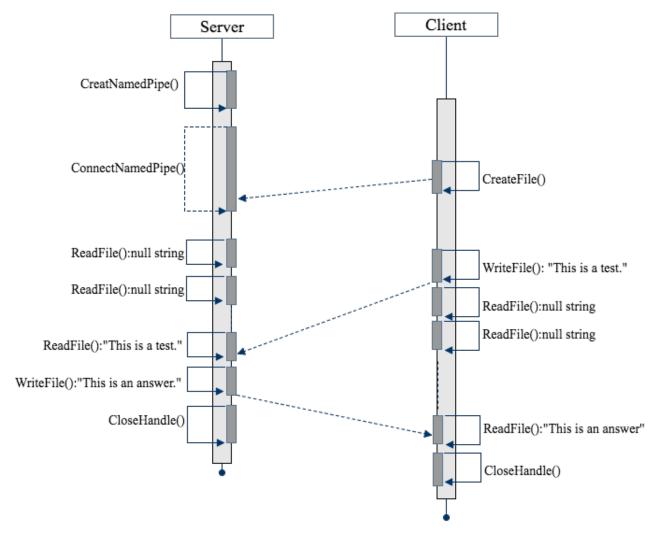

Figure 6.1: Sequence Diagram of Experiment 1

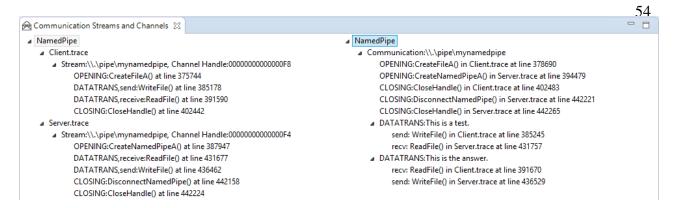

Figure 6.2: Identification result of exp1

6.1.2 Experiment 2

In the second experiment, one program was running as the Named pipe server. In this server program, four named pipes were created and can be connected by up to four client at a time. Two other programs as the Named pipe clients connected to this server. Those two clients (client 1 and client 2) used the identical program but run in sequence. Figure 6.3 is the sequence diagram of the interaction among the server and clients. The function calls' sequence is only a possible combination from analyzing the source code. The real happening sequence can varies. Traces were captured at the time when these three programs were running and interacting. One trace for each program. The three traces are analysed as two dual_traces, exp2.1 and exp2.2. exp2.1 consists of traces of server and client 1 and exp2.2 consists of traces of server and client 2. I ran the "Stream identification" and "Communication identification" operations for these two dual_trace. The identified streams and communications are shown in Figure 6.4 and Figure 6.5.

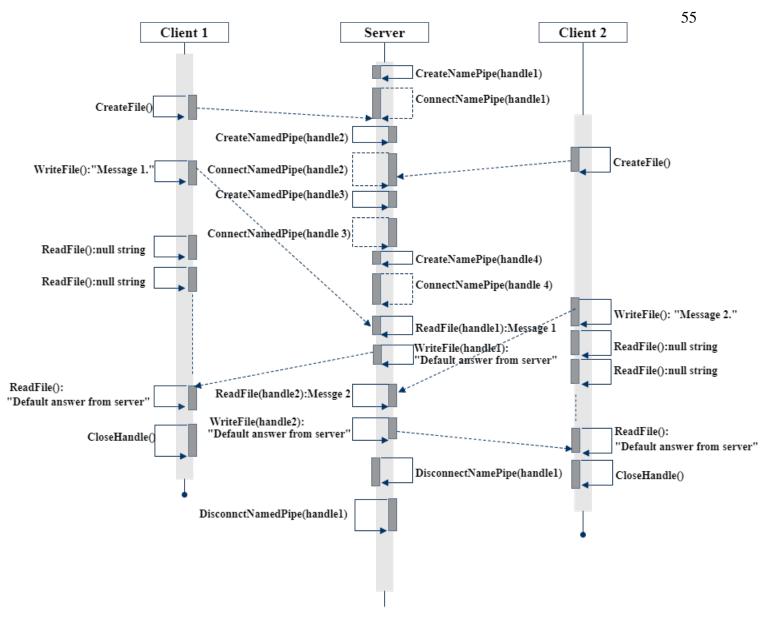

Figure 6.3: Sequence Diagram of Experiment 2

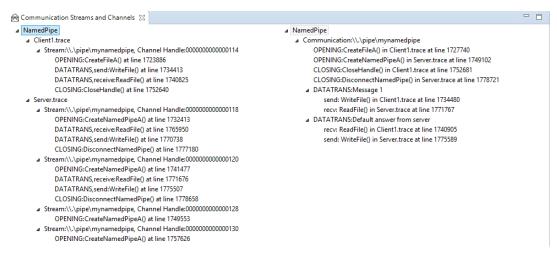

Figure 6.4: Identification result of exp2.1

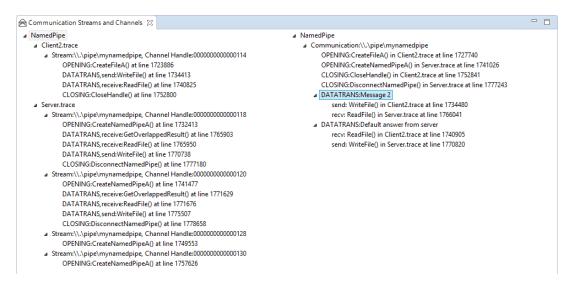

Figure 6.5: Identification result of exp2.1

6.2 Discussion

In the result of exp1, there are one stream extracted in client trace and one in server trace, and these two streams are matched into a communication of this dual_trace. This identification result represents the actual communication happen between the named pipe server and client. In the result of exp2.1 and exp2.2, there are one stream in each of the client traces and four in the server trace respectively. The streams are further matched and verified and eventually one communication is identified for each dual_trace. The result aligns to the sequence diagram in Figure 6.3.

Chapter 7

Conclusions and Future Work

In this thesis, I present the approach of communication analysis through assembly level execution traces. I first defined the communication model. This abstract model depicts the outline of a communication between two running program, which gives the ground rule for the communication analysis. Then I depicted the general definition of the dual_trace, the definition indicate that all traces comply to this definition can be used to conducted the communication analysis.

I also developed the essential algorithms for the communication identification. The high level algorithm is generalizable for all communication methods' identification while the event stream extraction and matching algorithm are distinct for each communication method according to their channel open and data transfer mechanisms. However, the developed algorithms provides clear and referable examples to develop your own algorithm for communication methods which are not discussed in this thesis.

On top of the existing execution trace analysis environment Atlantis, I implemented the communication identification features. This feature provides the users a way to extend their concerned communication methods through the configuration file. The user interface allows the users to conduct the communication and stream identification from the dual_traces and navigate back from the identified result to the views of the trace in Atlantis. This feature prototype is a novel feature for conducting multiple trace analysis for reverse engineering at the time when this thesis was written. The experiments conducted in this work preliminary proves the usability of the model and the algorithms.

This thesis illustrates the novel idea and approach for dynamic program analysis which considerate the interaction of two programs. This idea is valuable due to the fact that programs or malware in the real world work collaboratively. The analysis of the communication and interaction of the programs provide more reliable information for vulnerability detection and program

analysis.

Future work can be divided in two directions. One is extending the model to be more generalize for all kinds of interaction but not only the message transferring communications while the other is conducting user studies of the communication analysis approach and the feature design to get a more concrete result of their usefulness.

Appendix A

Microsoft x64 Calling Convention for C/C++

- RCX, RDX, R8, R9 are used for integer and pointer arguments in that order left to right.
- XMM0, 1, 2, and 3 are used for floating point arguments.
- Additional arguments are pushed on the stack left to right. . . .
- Parameters less than 64 bits long are not zero extended; the high bits contain garbage.
- Integer return values (similar to x86) are returned in RAX if 64 bits or less.
- Floating point return values are returned in XMM0.
- Larger return values (structs) have space allocated on the stack by the caller, and RCX then contains a pointer to the return space when the callee is called. Register usage for integer parameters is then pushed one to the right. RAX returns this address to the caller.

Appendix C

Code of the Parallel Editors

Two essential pieces of code are listed for the parallel editor. One is for splitting the editor area for two editors while the other is to get the active parallel editors later on for dual_trace analysis.

C.1 The Editor Area Split Handler

Listing C.1: code in OpenDualEditorsHandler.java

```
public class OpenDualEditorsHandler extends AbstractHandler {
     EModelService ms;
     EPartService ps;
     WorkbenchPage page;
  public Object execute(ExecutionEvent event) throws ExecutionException {
            IEditorPart editorPart = HandlerUtil.getActiveEditor(event);
            if (editorPart == null) {
                  Throwable throwable = new Throwable("No active editor");
                  BigFileApplication.showErrorDialog("No active editor", "Please open one file

    first", throwable);
                 return null;
            }
            MPart container = (MPart) editorPart.getSite().getService(MPart.class);
            MElementContainer m = container.getParent();
            if (m instanceof PartSashContainerImpl) {
                  Throwable throwable = new Throwable("The active file is already opened in one
                      \hookrightarrow of the parallel editors");
                  BigFileApplication.showErrorDialog("TThe active file is already opened in one
                      \hookrightarrow of the parallel editors",
                               "The active file is already opened in one of the parallel editors",
                  return null;
```

```
IFile file = getPathOfSelectedFile(event);
         IEditorDescriptor desc = PlatformUI.getWorkbench().getEditorRegistry().
             → getDefaultEditor(file.getName());
         try {
               IFileUtils fileUtil = RegistryUtils.getFileUtils();
               File f = BfvFileUtils.convertFileIFile(file);
               f = fileUtil.convertFileToBlankFile(f);
               IFile convertedFile = ResourcesPlugin.getWorkspace().getRoot().

    getFileForLocation(Path.fromOSString(f.getAbsolutePath()));
               convertedFile.getProject().refreshLocal(IResource.DEPTH_INFINITE, null);
               if (!convertedFile.exists()) {
                     createEmptyFile(convertedFile);
               }
               IEditorPart containerEditor = HandlerUtil.getActiveEditorChecked(event);
               IWorkbenchWindow window = HandlerUtil.getActiveWorkbenchWindowChecked(event);
               ms = window.getService(EModelService.class);

D.2 Experiment 2

In the experiment 2, two clients run the same program in sequence to connect to the server with asynchronous Named pipe channel. The first piece of code listed below is the code for the server's program while the second piece is the test.bat is the script for running the experiment. The client program's code is identical to experiment 1.

Listing D.3: NamedPipeServerOverlapped.cpp

```
#include <Windows.h>
